25 October 2009

ABSTRACT

We study the prospects for detecting neutrino masses from the galaxy angular power spectrum in photometric redshift shells of the Dark Energy Survey (DES) over a volume of $\sim 20 h^{-3} \text{ Gpc}^3$, combined with the Cosmic Microwave Background (CMB) angular fluctuations expected to be measured from the Planck satellite. We find that for a Λ -CDM concordance model with 7 free parameters in addition to a fiducial neutrino mass of $M_\nu = 0.24 \text{ eV}$, we recover from DES&Planck the correct value with uncertainty of $\pm 0.12 \text{ eV}$ (95 % CL), assuming perfect knowledge of the galaxy biasing. If the fiducial total mass is close to zero, then the upper limit is 0.11 eV (95 % CL). This upper limit from DES&Planck is over 3 times tighter than using Planck alone, as DES breaks the parameter degeneracies in a CMB-only analysis. The analysis utilizes spherical harmonics up to 300, averaged in bin of 10 to mimic the DES sky coverage. The results are similar if we supplement DES bands (grizY) with the VISTA Hemisphere Survey (VHS) near infrared band (JHK). The result is robust to uncertainties in non-linear fluctuations and redshift distortions. However, the result is sensitive to the assumed galaxy biasing schemes and it requires accurate prior knowledge of the biasing. To summarize, if the total neutrino mass in nature greater than 0.1 eV , we should be able to detect it with DES&Planck, a result with great importance to fundamental Physics.

Key words: large-scale structure of Universe – cosmological parameters – surveys

1 INTRODUCTION

Neutrinos are so far the only dark matter candidates that we actually know exist. It is now established from solar, atmospheric, reactor and accelerator neutrino experiments that neutrinos have non-zero mass, but their absolute masses are still unknown. Cosmology could provide an upper limit on the sum of neutrino masses (for review see e.g. Elgarøy & Lahav 2005; Lesgourgues & Pastor 2006). The growth of Fourier modes with comoving wavenumber $k > k_{\text{nr}}$ will be suppressed because of neutrino free-streaming, where

$$k_{\text{nr}} = 0.026 \left(\frac{m_\nu}{1 \text{ eV}} \right)^{1/2} \Omega_{\text{m}}^{1/2} h \text{ Mpc}^{-1}, \quad (1)$$

for three equal-mass neutrinos, each with mass m_ν .

The current mass upper limit, obtained using Cosmic Microwave Background (CMB) WMAP5 data, SN Ia and the BAO from 2dFGRS and SDSS, is $M_\nu \equiv \sum m_\nu < 0.61 \text{ eV}$ at 95% CL (Komatsu et al. 2009). The challenge now is to bring down reliably the upper limits to the 0.1 eV level or even detect the neutrino mass. In this way Cosmology could resolve the mass scale of neutrinos. The new generation of deep wide surveys can play a key role in setting a tight upper limit on the neutrino mass, and possibly detect it if the true neutrino mass is sufficiently high. This is due to the order of magnitude increase in volume of the new surveys.

Here we study specifically the ability to set an upper limit on the neutrino mass from the galaxy clustering expected in the photometric redshift survey Dark Energy Survey (DES), combined with Planck CMB measurements. The reason a survey like DES would be effective is its large vol-

* E-mail: lahav@star.ucl.ac.uk

ume, $\sim 20 h^{-3} \text{ Gpc}^3$, and large number of galaxies, ~ 300 million.

Crudely, for a spectroscopic survey, where accurate redshifts are known, the error on the power spectrum scales with the survey effective volume V_{eff} as

$$\Delta P(k)/P(k) \propto 1/\sqrt{V_{\text{eff}}}. \quad (2)$$

On the other hand, the suppression is proportional in the linear regime to $f_\nu = \Omega_\nu/\Omega_m$ (Hu et al. 1998; Kiakotou et al. 2008), where

$$\Omega_\nu = \frac{\Sigma_i m_i}{93.14 h^2 \text{ eV}}. \quad (3)$$

We expect therefore (when all other cosmological parameters are fixed) that the determination of the upper limit on the neutrino mass would be inversely proportional to $\sqrt{V_{\text{eff}}}$. From the 2dF Galaxy spectroscopic redshift survey, covering a volume of roughly $0.2 (h^{-1} \text{ Gpc})^3$, the upper limit on the sum of neutrino mass is about 2 eV at 95 % CL (Elgarøy et al. 2002). Had DES been a spectroscopic survey with volume of about $20 (h^{-1} \text{ Gpc})^3$, i.e. 100 times larger, we would expect an upper limit of 0.2 eV on the sum of neutrino mass. Our detailed calculation below yields an upper limit of 0.1eV for DES&Planck. This is tighter than the above back-of-the-envelope calculation, probably as Planck priors are incorporated, and the effective volumes above are only given crudely.

However, DES is photometric redshift survey, so the radial component of distance to galaxies is significantly degraded, resulting in a poorer estimate of the power spectrum (e.g. Blake & Bridle 2005). Therefore we prefer in this analysis to quantify the galaxy clustering as angular (spherical harmonic) C_ℓ power spectrum derived in photometric redshift shells which are wide enough relative to the photometric redshift errors, and to derive the resulting upper limits more carefully and quantitatively. We defer the comparison of $P(k)$ and C_ℓ approaches to future studies. The utility of photometric redshifts is now well-established, with many successful techniques being employed (e.g. Collister & Lahav 2004; Abdalla et al. 2009). The cosmological parameter constraints resulting from future photometric redshift imaging surveys have been simulated by several authors (e.g. Seo & Eisenstein 2003; Dolney et al. 2004; Zhan et al. 2006). Application to data such as the SDSS LRG samples were given by Blake et al. (2007) and Padmanabhan et al. (2007). These studies mainly emphasized the detection of baryon acoustic oscillations in the galaxy clustering pattern. Apart from the specific application to DES, the present paper illustrates more generally the determination of neutrino mass from photo-z surveys, to our knowledge for the first time.

This paper is organized as follows. In Sections 2 we summarize the DES and VHS surveys and Planck, in Section 3 we present the photometric redshifts for DES and DES& the Vista Hemisphere Survey (VHS) combined filters. Sections 4 give the formalism for the galaxy angular power spectrum, and the associated joint likelihood with Planck. Section 5 presents the results for the basic observational and theoretical scenarios, while Section 6 provides extensions of the analysis. An overall discussion is given in Section 7.

2 THE GALAXY SURVEYS

2.1 The Dark Energy Survey (DES)

The Dark Energy Survey (www.darkenergysurvey.org) is a ground-based photometric survey that will image 5000 deg^2 of the South Galactic Cap in the optical *griz* bands as well as the Y-band. The survey will be carried out using the Blanco 4-m telescope at the Cerro Tololo Inter-American Observatory (CTIO) in Chile. The main objectives of the survey are to extract information on the nature and density of dark energy and dark matter using galaxy clusters, galaxy power spectrum measurements, weak lensing studies and a supernova survey. This will be achieved by measuring redshifts of some 300 million galaxies in the redshift range $0 < z < 2$, tens of thousands of clusters in the redshift range $0 < z < 1.1$ and about 2000 Type 1a supernovae out to redshift $z \approx 1$. Observations will be carried out over 525 nights spread over five years between 2011 and 2016. The DES volume is estimated to be $23.7 h^{-3} \text{ Gpc}^3$ in the range $0 < z < 2$ assuming a 10σ AB magnitude $r < 24$ (Banerji et al. 2008).

The DES survey area overlaps with that of several other important current and future surveys for example the southern equatorial strip of the Sloan Digital Sky Survey and the South Pole Telescope SZE cluster survey.

2.2 The Vista Hemisphere Survey (VHS)

The entire DES region will also be imaged in the near infra-red bands on two public surveys being conducted on the Visible and Infra-Red Survey Telescope for Astronomy (VISTA) at ESO's Cerro Paranal Observatory in Chile. In particular, the Vista Hemisphere Survey (VHS) (www.vista.ac.uk) will image the entire southern sky ($\sim 20000 \text{ deg}^2$) in the near infra-red *YJHK_s* bands when combined with other public surveys. About 40% of the total VHS time has been dedicated to VHS-DES, a 4500 deg^2 survey being carried out in the DES region over 125 nights in order to complement the DES optical data with near infra-red data. The initial proposal is for the survey to image in the *JHK_s* bands with 120s exposure times in each band reaching 10σ magnitude limits of $J = 20.4, H = 20.0$ and $K_s = 19.4$. A second pass may then be obtained with 240s exposures in each of the three NIR filters in order to reach the full-depth required by DES. The VHS-DES survey assumes that Y-band photometry will come from the Dark Energy Survey.

2.3 Planck

The recently launched ESA's Planck satellite will map the CMB with better resolution, sensitivity and frequency (in nine bands from one centimeter to one third of a millimeter) than previous CMB experiments [†].

We have obtained forecasts from the Planck satellite by using the technique described in (Abdalla & Rawlings 2007). We have assumed conservative values for the sensitivity by taking only one usable science channel with 8 detectors, a noise effective temperature of $120 \mu K \sqrt{s}$, an angular resolution of 10 arcminutes, and 65% sky coverage in a one year survey. The input fiducial masses are taken as

[†] <http://www.esa.int/SPECIALS/Planck>

Ω_ν	Ω_c	Ω_b	h	σ_8	n_s	τ	N_ν
0.005	0.255	0.04	0.72	0.9	1	0.166	2.0
0.001	0.259	0.04	0.72	0.9	1	0.166	2.0

Table 1. The two fiducial models in the Planck simulations. All these 8 parameters vary in the Planck MCMC chain. A flat universe is assumed. N_ν is the number of massive neutrinos. We note the value of the optical depth τ assumed here is based on WMAP1, higher than the most recent value estimated from WMAP5.

Figure 1. Gaussian fits to the true redshift distribution of in each of seven photometric redshift slices analyzed in this study. The best-fitting Gaussian parameters μ and σ are indicated, where $p(z) \propto \exp\{-(z - \mu)^2/2\sigma^2\}$.

$\Omega_\nu = 0.001$ and 0.005 , and the other cosmological parameters considered as listed in Table 1.

3 PHOTOMETRIC REDSHIFTS

We determined photometric redshift estimates as described in Banerji et al. (2008) using mock samples of DES and VHS and the photo-z software package “ANNz” (Collister & Lahav 2004). In brief, artificial neural networks are applied to parameterize a non-linear relation between the galaxy redshift and the galaxy multi-band photometry. The neural network is “trained” using a set of galaxies with known true redshifts by minimizing the sum of the squared differences between the photometric and true redshifts. For comparison of ANNz with 5 other photoz codes see Abdalla et al. (2009).

Figure 1 shows the distribution of true redshifts in the evaluation set for galaxies binned in seven photometric-redshift slices, as given in Table 2. We find that these error distributions are well fitted by Gaussian distributions; the best-fitting values of the mean and standard deviation for the different slices are indicated in the Table. These Gaussian functions are taken as our model for the redshift distribution of galaxies in each photo-z slice when analyzing the galaxy clustering results.

4 THE ANGULAR POWER SPECTRUM IN PHOTO-Z SHELLS

4.1 Spherical Harmonic Formalism

It is common to expand the distribution of galaxies in spherical harmonic coefficients $a_{\ell,m}$, which are then averaged to form the angular power spectrum C_ℓ

$$\langle |a_{\ell,m}|^2 \rangle = C_\ell. \quad (4)$$

(see e.g. Peebles 1973; Scharf et al. 1992; Wright et al. 1994; Wandelt et al. 2001).

The angular power spectrum C_ℓ is a projection of the spatial power spectrum of fluctuations at different redshifts z , $P(k, z)$, where k is a co-moving wavenumber. When the sky coverage is incomplete the prediction for observed angular power spectrum can be estimated through convolution, as explained later in the paper.

We follow here the notation of (Blake et al. 2007). The equation for the projection is:

$$C_\ell = \frac{2b^2}{\pi} \int P_0(k) g_\ell(k)^2 dk \quad (5)$$

where we assume $P(k, z) = P_0(k) D(z)^2$, with $D(z)$ the linear growth factor at redshift z , and $g_\ell(k)$ contains $D(z)$ as defined below.

We note that this decomposition of $P(k, z)$ is strictly only valid in linear theory, and its application at smaller scales is an approximation. Moreover, in the presence of massive neutrinos $P(k, z)$ cannot be decomposed even in linear theory. However, we find that over the redshift $z < 2$ and k -range of interest $P(k, z) \approx P_0(k) D(z)^2$ to within 0.5% (cf. Lesgourgues & Pastor 2006; Kiakotou et al. 2008). We have also assumed in the above equation a scale-independent and epoch-independent bias factor b . Later we allow the biasing to vary with redshift.

Figure 2 shows the expected spherical harmonic C_ℓ (ignoring shot noise) for three values of assumed neutrino mass, illustrating that the suppression effect can be measured. Figure 3 shows the expected C_ℓ ’s for three photo-z shells.

Similarly, $C_\ell^{i,j}$ is the cross angular power spectrum between the two redshift slices i and j , with a kernel $g_\ell^i(k)$ for a redshift slice i :

$$C_\ell^{i,j} = \frac{2b_i b_j}{\pi} \int P_0(k) g_\ell^i(k) g_\ell^j(k) dk \quad (6)$$

where b_i and b_j are the linear bias factors for the slices. The kernel $g_\ell(k)$ is given by:

$$g_\ell(k) = \int_0^\infty j_\ell(u) f(u/k) du. \quad (7)$$

Here, $j_\ell(x)$ is the spherical Bessel function and $f(x)$ depends on the radial distribution of the sources as

$$f[z(x)] = p(z) D(z) \left(\frac{dx}{dz} \right)^{-1} \quad (8)$$

where $x(z)$ is the co-moving radial co-ordinate at redshift z , and $p(z)$ is the redshift probability distribution of the sources, normalized such that $\int p(z) dz = 1$. A good approximation for equation 5 which is valid for moderately large $\ell \gtrsim 30$ is:

photo-z shell	galaxy fraction	DES		DES&VHS	
		mean	σ	mean	σ
$0.3 < z_{ph} < 0.5$	0.211	0.405	0.125	0.412	0.145
$0.5 < z_{ph} < 0.7$	0.337	0.582	0.125	0.598	0.129
$0.7 < z_{ph} < 0.9$	0.215	0.789	0.123	0.805	0.113
$0.9 < z_{ph} < 1.1$	0.128	0.975	0.125	0.984	0.116
$1.1 < z_{ph} < 1.3$	0.098	1.203	0.220	1.193	0.142
$1.3 < z_{ph} < 1.5$	0.081	1.393	0.260	1.393	0.147
$1.5 < z_{ph} < 1.7$	0.027	1.673	0.291	1.593	0.149

Table 2. The best-fitting Gaussian parameters μ and σ , in true redshift z , where $p(z) \propto \exp\{-(z - \mu)^2/2\sigma^2\}$ for photo-z shells derived from DES alone (5 filters) and DES&VHS (8 filters).

Figure 2. The model angular power spectrum for the photometric redshift slice $z = 0.8$ with the exact expression in real space (equation 5 with the kernel of equation 7). The curves are for three values of $\Omega_\nu = 0.000, 0.001$ and 0.005 , with the other cosmological parameters held fixed at the values given in Table 1.

$$C_\ell = b^2 \int P_0(k = \ell/x) D^2(z) x(z)^{-2} p(z)^2 \left(\frac{dx}{dz}\right)^{-1} dz. \quad (9)$$

The above formalism neglects redshift distortions, which we examine later.

The cosmological parameters enter the matter power spectrum of fluctuations $P_0(k)$, the growth factor $D(z)$ and the co-moving distance $x(z)$ in the above equations. For the redshift distribution of the sources $p(z)$ we used the Gaussian functions fitted to the training set data (see Figure 1). We derived model spatial power spectra using the “CAMB” software package (Lewis et al. 2000). For more technical details of these calculations see (Blake et al. 2007).

4.2 Spherical Harmonic Likelihood

In this work we forecast the measurements, without any data, so we use the following relation to express the ratio of (log) probabilities between a selected model in the parameter space B and the assumed fiducial model A. The model describes all the power spectra produced from random Gaussian fields with a certain degree of cross correlation (Bucher et al. 2002; Abdalla & Rawlings 2007).

Figure 3. The model angular power spectrum for three photometric redshift slices centered at $z = 0.4, 0.8$ and 1.6 . The curves are for $\Omega_\nu = 0.005$, with the other cosmological parameters held fixed at the values given in the first row Table 1. The amplitude difference between these curves is partially due to the growth of structure with redshift and partially due to the variation in the photo-z error with redshift.

$$\begin{aligned} \log\left(\frac{p_B}{p_A}\right) &= \log\left(\frac{p(a_{lm}|B)}{p(a_{lm}|A)}\right) \\ &= \frac{f_{\text{sky}}}{2} \sum_l (2l+1) \left(\text{Tr}(I - M_A M_B^{-1}) + \log(\text{Det}(M_A M_B^{-1})) \right) \end{aligned} \quad (10)$$

where I is the identity matrix and the matrices M_A and M_B are given by the values of the individual power spectra and their cross correlations at a given mode l . As in our case we have 7 shells each of them is a 7×7 matrix. The diagonal terms are

$$\text{diag}(M_l) = C_l + \sigma_l^2, \quad (11)$$

where $\sigma_l^2 = \frac{1}{N/\Delta\Omega}$ where $N/\Delta\Omega$ is the average source density and $f_{\text{sky}} = \Delta\Omega/(4\pi)$ denotes the fraction of sky covered by the survey. There is no shot-noise in the off-diagonal terms.

To get insight into this likelihood ratio we note the special case of eq. 10 for a shell’s auto-correlation (cf.

Fisher et al. 1994):

$$\begin{aligned} \log\left(\frac{p_B}{p_A}\right) &= \log\left(\frac{p(a_{lm}|B)}{p(a_{lm}|A)}\right) \\ &= \frac{f_{sky}}{2} \sum_l (2l+1) \left(1 - \frac{C_{l,A} + \sigma_l^2}{C_{l,B} + \sigma_l^2} + \log\left(\frac{C_{l,A} + \sigma_l^2}{C_{l,B} + \sigma_l^2}\right)\right). \end{aligned} \quad (12)$$

5 ANALYSIS AND RESULTS

The joint likelihood is implemented as follows. The Planck MCMC chain in 8-dimensional space is centred at one of the two fiducial models given in Table 1. The DES likelihood is evaluated using eq. 10, with label A corresponding to the fiducial model, and label B to another point of the Planck chain. By evaluating the DES likelihood at the Planck chain points we effectively get the joint likelihood of DES & Planck. If we are interested in a subset of the parameters of interest we can easily marginalize over the other parameters by projecting the distribution of the points in the resulting chain.

We first consider a baseline model so we can see “the wood for the trees”, where we assume a linear matter power spectrum (derived from CAMB), a linear biasing parameter $b = 1$ for all 7 photo- z slices, no redshift distortion, and we ignore the mask. In the discussion below we refer to the 95% CL values.

The first entry in Table 3 is for Planck alone, while the second entry is for Planck & DES, both for $l = 1, 2, \dots, 100$. We see that the addition of DES improves the upper limit to 0.11 eV, more than 3 times tighter than Planck alone. The corresponding error bar on the high-mass values is 0.13 eV from Planck & DES. The likelihood contours in Figures 4,5,6 correspond to entry 5 in Table 3, where $\ell_{max} = 300$, where $\Delta\ell = 10$, which roughly represents the DES incomplete sky, with fiducial $\Omega_\nu = 0.001$ and $\Omega_\nu = 0.005$. They show pairs of variables (Ω_ν, σ_8) , (Ω_ν, h) , and (Ω_ν, Ω_b) , and in Figure 7 the probability for Ω_ν , after marginalizing over all other seven parameters. Numerical results are given in Table 3, as 68 % and 95 % upper limits. We note the similarity of results of entries 2 and 5 in that Table. We also note that in the case of entry 5, the 5- σ upper limit is 0.121 eV, compared with the 2- σ value of 0.106 eV.

6 EXTENSIONS OF THE ANALYSIS

6.1 Incomplete sky coverage

When the sky coverage is incomplete the prediction for observed angular power spectrum can be estimated through convolution:

$$\langle C_\ell^{obs} \rangle = \sum_{\ell'} R_{\ell, \ell'} C_{\ell'} \quad (13)$$

where the “mixing matrix” $R_{\ell, \ell'}$ can be determined from the angular power spectrum of the survey window function. For a survey of 5000 sq deg or so the mixing matrix smears out harmonics over $\Delta\ell \approx 10$, subject to survey’s geometry (Blake et al. 2007). We illustrate the effect of incomplete sky

Figure 4. The likelihood contours show Ω_ν and σ_8 from Planck alone and Planck & DES, with fiducial $\Omega_\nu = 0.001$ (top) and $\Omega_\nu = 0.005$ (bottom). The likelihood functions are evaluated for $\ell_{max} = 300$, where $\Delta\ell = 10$ (corresponding to entry 5 in Table 3). These plots are for seven cross-correlated DES shells. Contours show 68% CL and 95% CL. The sensitivity to the assumed galaxy biasing scheme is illustrated with the point O corresponds to $b = 1.00$, X corresponds to $b = 1.02$ constant for all shells, and Y corresponds to epoch-dependent $b(z)$ from eq 19 with $b_0 = 1.02$.

coverage by averaging the angular power spectra in multipole bands of width $\Delta\ell = 10$:

$$\langle C_\ell^{av} \rangle = \sum_{\ell'} (2\ell' + 1) C_{\ell'} / \sum_{\ell'} (2\ell' + 1) \quad (14)$$

Entry (4) in Table 3 shows that the upper limit on the neutrino mass is twice as large as for a ‘whole sky DES’ (entry 2 in Table 3). However, if we use harmonics up to $\ell_{max} = 300$ (entry 5), then the upper limits are very similar to those in entry (2), where $\ell_{max} = 100$.

6.2 DES & VHS photoz

Entries (7) and (8) in Table 3 illustrate the impact of adding VHS near infrared photometry, i.e. having photo- z based on 8 filters. It turns out that the results on neutrino mass look very similar to DES alone. This is because the improvement of VHS is at high redshift (Banerji et al. 2008) and the high redshift shells have higher shot noise and hence are weighted less in the likelihood analysis.

6.3 Redshift distortion

These distortions significantly affect the amplitude of the projected power spectrum on large scales $\ell \lesssim 50$, owing to

	l_{min}	l_{max}	Δl	$M_\nu=0.048$ eV		$M_\nu=0.241$ eV	
				68%CL	95%CL	68%CL	95%CL
(1) Planck	1	100	1	$M_\nu < 0.175$	$M_\nu < 0.386$	$0.034 < M_\nu < 0.391$	$0.0041 < M_\nu < 0.616$
(2) Planck&DES	1	100	1	$M_\nu < 0.067$	$M_\nu < 0.112$	$0.172 < M_\nu < 0.304$	$0.113 < M_\nu < 0.380$
(3) Planck&DES	20	120	1	$M_\nu < 0.063$	$M_\nu < 0.101$	$0.176 < M_\nu < 0.296$	$0.124 < M_\nu < 0.362$
(4) Planck&DES	1	100	10	$M_\nu < 0.106$	$M_\nu < 0.216$	$0.109 < M_\nu < 0.354$	$0.014 < M_\nu < 0.476$
(5) Planck&DES	1	300	10	$M_\nu < 0.063$	$M_\nu < 0.106$	$0.169 < M_\nu < 0.291$	$0.113 < M_\nu < 0.354$
(6) Planck&DES	1	300	1	$M_\nu < 0.052$	$M_\nu < 0.079$	$0.181 < M_\nu < 0.275$	$0.136 < M_\nu < 0.322$
(7) Planck&DES&VHS	1	100	1	$M_\nu < 0.066$	$M_\nu < 0.110$	$0.174 < M_\nu < 0.304$	$0.117 < M_\nu < 0.379$
(8) Planck&DES&VHS	1	300	10	$M_\nu < 0.061$	$M_\nu < 0.101$	$0.171 < M_\nu < 0.291$	$0.117 < M_\nu < 0.353$

Table 3. Table showing derived results neutrino mass M_ν for two input fiducial values $M_\nu = 0.048$ eV and 0.241 eV. The results are given for different combination of mock data sets (DES, VHS, Planck) and different range of spherical harmonics l_{min}, l_{max} and smoothing scale Δl .

Figure 5. The likelihood contours show Ω_ν and h from Planck alone and Planck & DES, with fiducial $\Omega_\nu = 0.001$ (top) and $\Omega_\nu = 0.005$ (bottom). The likelihood functions are evaluated for $\ell_{max} = 300$ and $\Delta\ell = 10$. These plots are for seven cross-correlated DES shells. Contours show 68% CL and 95% CL.

the relative narrowness of each redshift slice. The amplitude of the redshift-space distortions is controlled by a parameter $\beta(z) \approx \Omega_m(z)^{0.6}/b(z)^\dagger$, where the quantities on the right-hand side of the equation are evaluated at the centre of each redshift slice of our analysis. The effect is to introduce an additional term to the kernel of equation 7 such that it becomes $g_\ell(k) + g_\ell^\beta(k)$ where:

[†] For a more accurate expression in the presence of neutrinos see Kiakotou et al. (2008), but this correction is negligible for the qualitative argument presented here.

Figure 6. The likelihood contours show Ω_ν and Ω_b from Planck alone and Planck & DES, with fiducial $\Omega_\nu = 0.001$ (top) and $\Omega_\nu = 0.005$ (bottom). The likelihood functions are evaluated for $\ell_{max} = 300$ and $\delta\ell = 10$. These plots are for seven cross-correlated DES shells. Contours show 68% CL and 95% CL.

$$g_\ell^\beta(k) = \frac{\beta}{k} \int_0^\infty j'_\ell(u) f'(u/k) du \quad (15)$$

(Fisher et al. 1994; Padmanabhan et al. 2007; Blake et al. 2007).

Figure 8 shows that the redshift distortion is important for $\ell < 20$. In entry 3 of Table 3 we show the effect of analysing $20 < \ell < 120$. Excluding the low ℓ changes only little the results on neutrino mass compared with the case where low- ℓ are included (entry 2).

Figure 7. The probability for the neutrino mass density Ω_ν , with fiducial $\Omega_\nu = 0.001$ and $\Omega_\nu = 0.005$, after marginalizing over the other 7 free parameters, for the cases of Planck alone and Planck & DES.

Figure 8. Real-space (bottom) vs redshift space (top) for the nearest ($z = 0.4$) shell assuming $\Omega_\nu = 0.005$ and the other cosmological parameters as in Table 1. The curves are normalized to agree at high l . The assumed biasing is $b = 1$.

6.4 Non-linear power spectrum

Typically, non-linearity in the power spectrum appears for $k > k_{\max} \approx 0.15 h \text{ Mpc}^{-1}$, at $z = 0$ (e.g. Smith et al. 2003) and higher $k_{\max}$ at higher redshifts. We can estimate the equivalent maximum multipole $\ell_{\max}$ of the angular power spectrum using the scaling relation $k_{\max} = \ell_{\max}/r(z)$ (see equation 9). For example, for the shells with mean redshift $z \approx 0.4, 0.8$ and 1.6 and assuming a flat universe with $\Omega_m = 0.25$ this corresponds to $\ell_{\max} \approx 160, 290$ and 510 . Roughly

Figure 9. linear power spectrum (solid line) vs non-linear power spectrum according to Eq. 17 (dashed line) for the nearest ($z = 0.4$) shell, assuming $\Omega_\nu = 0.005$ and the other cosmological parameters as in Table 1. The curves are normalized to agree at $l = 1$. The envelope of error bars is derived from Eq. 18.

speaking it is safe to assume linear theory up to those $\ell_{\max}$ values.

To check the justification of this simple approximation, we considered a non-linear power spectrum in the presence of massive neutrinos. The total matter density fluctuation can be written as

$$\delta_m = f_{cb}\delta_{cb} + f_\nu\delta_\nu, \quad (16)$$

where $f_{cb} = 1 - f_\nu$ is the fractional contribution of the CDM plus baryon of the present epoch mass density. The resulting non-linear power spectrum can be approximated (Saito et al. 2008, 2009; Ichiki et al. 2009) as

$$P_m^{\text{nl}}(k) = f_\nu^2 P_\nu^L(k) + (1 - f_\nu)^2 P_{cb}^{NL}(k) + 2f_\nu(1 - f_\nu)P_{cb,\nu}^L(k), \quad (17)$$

where superscripts L and NL denote linear and non-linear power spectra respectively, and $P_{cb,\nu}^L(k)$ is a cross power spectrum neutrino and CDM plus baryons.

This approximation is convenient, as the non-linear $P_{cb}^{NL}(k)$ can be taken from fits to N-body simulations ((Saito et al. 2008) based on (Smith et al. 2003); “**halofit** = 1” in **CAMB**). Assuming linearity for the power spectra which involve neutrino mass is reasonable, as due to their free streaming, massive neutrinos remain in the linear regime, rather than joining the non-linear evolution of CDM plus baryons. We also note that the pre-factor f_ν is small, which justifies further ignoring non-linear neutrino perturbations. For a slightly different approximation see (Hannestad et al. 2006).

For comparison we plot in Figure 9 the errors on the C_ℓ ’s (e.g. Dodelson 2003; Blake et al. 2007):

$$\sigma(C_\ell) = \sqrt{(2/f_{\text{sky}}/(2\ell + 1))(C_\ell + \frac{1}{N/\Delta\Omega})}, \quad (18)$$

which are far larger than the non-linearity effect for $\ell < 100$. As Figure 10 shows the that in this regime the effect of non-linearity is less than 5 %.

6.5 Epoch dependent biasing

Another source of uncertainty in constraining neutrino mass from galaxy surveys is galaxy biasing (e.g. Elgarøy & Lahav

Figure 10. The ratio of C_l 's with non-linear to linear power spectra according to Eq. 17 including epoch dependence (solid line) for 4 shells, assuming $\Omega_\nu = 0.005$ and the other cosmological parameters as in Table 1. The curves are normalized to agree at $l = 1$. We see that up to $l = 100$ the effect of non-linear power spectrum is less than 5 %.

2005). The bias systematically increases with redshift for two reasons:

(i) In standard models of the evolution of galaxy clustering, the bias factor of a class of galaxies increases with redshift in opposition to the decreasing linear growth factor, in order to reproduce the observed approximate constancy of the small-scale clustering length (e.g. Magliocchetti et al. 2000; Lahav et al. 2002).

(ii) In a flux limited survey galaxies in more distant redshift slices are preferentially more luminous (owing to the fixed apparent magnitude threshold) and hence more strongly clustered (Norberg et al. 2002).

Here we test what happens if the biasing varies with epoch. One simple model is the ‘galaxy evolving model’ (Fry 1996), where the bias evolves as:

$$b(z) = 1 + (b_0 - 1)/D(z) \quad (19)$$

where b_0 is the present galaxy bias for a particular galaxy type, and $D(z)$ is the linear theory growth rate.

The sensitivity to the assumed galaxy biasing scheme is illustrated in Figure 4 (bottom). The point O corresponds to $b = 1.00$ in the fiducial model for all shells, X corresponds to $b = 1.02$, and Y corresponds to epoch-dependent $b(z)$ from Eq. 19 with $b_0 = 1.02$. According to that plot, if b deviates from unity by more than 2% then σ_8 changes by 2% and Ω_ν changes by 7%. Therefore biasing is the most sensitive quantity in our analysis. In other words, we need to have the bias known to 2 per cent accuracy as a larger bias would introduce a best fit value outside the one sigma error bar in figure 4.

We see that our results are sensitive to biasing. Fortunately there are several independent ways of controlling this systematic effect : (i) modelling the biasing via halo model or semi-analytic simulations, and marginalising over the biasing parameters; (ii) estimating the neutrino mass from galaxy power-spectra derived for different galaxy types and checking for consistency; (iii) estimating the biasing empirically from weak-lensing map to be produced e.g. from DES

itself; (iv) estimating biasing from high order statistic such as the bi-spectrum.

7 CONCLUSIONS

We study the prospects for detecting neutrino masses from the galaxy angular power spectrum in photo- z shells in the Dark Energy Survey, combined with CMB fluctuations as will be measured by Planck. Although the core science case for DES is Dark Energy, we see that DES can provide us with other important extra science, such as neutrino mass. Our main conclusions are:

- We forecast for DES&Planck a 2-sigma error of total neutrino mass $\Delta M_\nu \approx 0.12$ eV. If the true neutrino mass is very close to zero, then we can obtain an upper limit of 0.11 eV (95% CL).
- This upper limit from DES+Planck is over 3 times tighter than using Planck alone, as DES breaks the parameter degeneracies in a CMB-only analysis.
- The results are sensitive to the assumed galaxy biasing, and stand if the galaxy bias is known to within 2 per cent. This is feasible given other analyses of the galaxy bias such as the three point correlation function (Ross et al. 2007).
- The results are robust to uncertainties in non-linear fluctuations and redshift distortion.
- The results are similar if we supplement DES bands (grizY) with the VISTA Hemisphere Survey (VHS) near infrared band (JHK).

DES can also be used to extract information on neutrino mass via other techniques, e.g. weak gravitational lensing, as considered recently for other imaging surveys (Kitching et al. 2008; Ichiki et al. 2009). We note that the level of sensitivity for neutrino mass from DES& Planck is of much relevance for comparison with the direct measurement of the neutrino mass from laboratory experiments. E.g. the KATRIN tritium beta decay experiment. Furthermore, the DES & Planck measurements can be combined with laboratory experiments to derive more accurate neutrino masses (Host et al. 2007).

ACKNOWLEDGMENTS

We thank our DES collaborators for helpful discussions, S. Saito, M. Takada & A. Taruya for providing us with a code for a non-linear power spectrum, and S. Bridle, J. Thaler and S. Thomas for comments on the manuscript. OL acknowledges a Royal Society Wolfson Research Merit Award and an Erna & Jakob Michael Visiting Professorship at the Weizmann Institute of Science, AK acknowledges a Perren Studentship and FBA acknowledges a Leverhulme Early Career Fellowship.
